Abstract—The role of social media, in particular microblogging platforms such as Twitter, as a conduit for actionable and tactical information during disasters is increasingly acknowledged. However, time-critical analysis of big crisis data on social media streams brings challenges to machine learning techniques, especially the ones that use supervised learning. Scarcity of labeled data, particularly in the early hours of a crisis, delays the machine learning process. The current state-of-the-art classification methods require a significant amount of labeled data specific to a particular event for training plus a lot of feature engineering to achieve best results. In this work, we introduce neural network based classification methods for binary and multi-class tweet classification task. We show that neural network based models do not require any feature engineering and perform better than state-of-the-art methods. In the early hours of a disaster when no labeled data is available, our proposed method makes the best use of the out-of-event data and achieves good results.

Keywords—Deep learning, Neural networks, Supervised classification, Social media, Crisis response

I. INTRODUCTION

Time-critical analysis of social media data streams is important for many application areas [1], [2], [3]. During the onset of a crisis situation, people use social media platforms to post situational updates, look for useful information, and ask for help [4], [5]. Rapid analysis of messages posted on microblogging platforms such as Twitter can help humanitarian organizations like the United Nations gain situational awareness, learn about urgent needs of affected people, critical infrastructure damage, medical emergencies, etc. at different locations, and decide on response actions accordingly [6], [7].

Artificial Intelligence for Disaster Response¹ (AIDR) is an online platform to support disaster response utilizing big crisis data from social networks [8]. During a disaster, any person or organization can provide keywords to collect tweets of interest. Filtering using keywords helps cut down the volume of the data to some extent. But, identifying different kinds of *useful* tweets that responders can act upon cannot be achieved using only keywords because a large number of tweets may contain the keywords but are of limited utility for the responders. The best-known solution to address this problem is to use supervised classifiers that

would separate useful tweets from the rest and classify them accordingly into informative classes.

Automatic classification of tweets to identify useful tweets is a challenging task because: (i) tweets are short – only 140 characters – and therefore, hard to understand without enough context; (ii) they often contain abbreviations, informal language, spelling variations and are ambiguous; and, (iii) judging a tweet’s utility is a subjective exercise. Individuals differ on their judgment about whether a tweet is useful or not. Classifying tweets into different topical classes posits further difficulties because: (i) tweets may actually contain information that belongs to multiple classes; choosing the dominant topical class is hard; and, (ii) the semantic ambiguity in the language used sometimes makes it hard to interpret the tweets. Given these inherent difficulties, a computer cannot generally agree with annotators at a rate that is higher than the rate at which the annotators agree with each other. Despite advances in natural language processing (NLP), interpreting the semantics of the short informal texts automatically remains a hard problem.

To classify crisis-related data, traditional classification approaches use batch learning with discrete representation of words. This approach has three major limitations. First, in the beginning of a disaster situation, there is no event labeled data available for training. Later, the labeled data arrives in small batches depending on the availability of geographically dispersed volunteers (e.g. in case of AIDR). These learning algorithms are dependent on the labeled data of the event for training. Due to the discrete word representations and the variety across events from which the big crisis data is collected, they perform poorly when trained on the data from previous events (*out-of-event data*). Second, training a classifier from scratch every time a new batch of labeled data arrives is infeasible due to the velocity of the big crisis data. Third, traditional approaches require manually engineered features like cue words and TF-IDF vectors [5] for learning. Due to the variability of the big crisis data, adapting the model to changes in features and their importance manually is undesirable (and often infeasible).

Deep neural networks (DNNs) are ideally suited for big crisis data. They are usually trained using online learning and have the flexibility to adaptively learn from new batches of labeled data without requiring to retrain from scratch. Due

¹<http://aidr.qcri.org/>

to their distributed word representation, they generalize well and make better use of the previously labeled data from other events to speed up the classification process in the beginning of a disaster. DNNs obviate the need of manually crafting features and automatically learn latent features as distributed dense vectors, which generalize well and have shown to benefit various NLP tasks [9], [10], [11], [12].

In this paper, we propose a convolutional neural network (CNN) for the classification tasks. CNN captures the most salient n -gram information by means of its convolution and max-pooling operations. On top of the typical CNN, we propose an extension that combines multilayer perceptron with a CNN. We present a series of experiments using different variations of the training data – event data only, out-of-event data only and a concatenation of both. Experiments are conducted for binary and multi-class classification tasks. For the event only binary classification task, the CNN model outperformed in all tasks with an accuracy gain of up to 7.5 absolute points over the best non-neural classification algorithm. In the scenario of no event data, the CNN model shows substantial improvement of up to 10 absolute points over several non-neural models. This makes the neural network model an ideal choice for classification in the early hours of a disaster when no labeled data is available. When combined the event data with the out-of-event data, overall results of all classification methods drop by a few points compared to using event only training.

For multi-class classification, we achieved similar results as in the case of binary classification. The CNN model outperformed other competitors. Our variation of the CNN model with multilayer perceptron (MLP-CNN) performed better than its CNN-only counterpart. Similar to binary classification, blindly adding out-of-event data either drops the performance or does not give any noticeable improvement over the event only model. To reduce the negative effect of large out-of-event data and to make the most out of it, we apply two simple domain adaptation techniques – 1) weight the out-of-event labeled tweets based on their closeness to the event data, 2) select a subset of the out-of-event labeled tweets that are correctly labeled by the event-based classifier. Our results show that later results in better classification model.

To summarize, we show that neural network models perform better than non-neural models for both binary and multi-classification scenario. They can be used reliably with the already available out-of-event data for binary and multi-class classification of disaster-related big crisis data. DNNs are better suited for big crisis data than conventional classifiers because they can learn features automatically and can be adopted to online settings.

The rest of the paper is organized as follows. We present the convolutional neural model for classification tasks in Section II. Section III presents the adaptation method. We describe the dataset and training settings of the models in

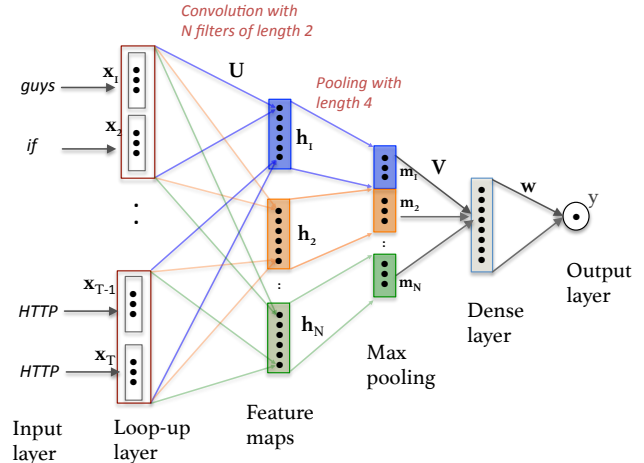

Figure 1: Convolutional neural network on a tweet.

Section IV. In Section V, we present our results and analysis. We provide an in-depth discussion on the obtained results in Section VI. We summarize related work in Section VII. We conclude and discuss future work in Section VIII.

II. CONVOLUTIONAL NEURAL NETWORK

When there is not enough in-event training data available, in order to classify short and noisy big crisis data effectively, a classification model should use a distributed representation of words. Such a representation results in improved generalization. The system should learn the key features at different levels of abstraction automatically. To this end, we use a Convolutional Neural Network (CNN). Figure 1 demonstrates how a CNN works with an example tweet “guys if know any medical emergency around balaju area you can reach umesh HTTP doctor at HTTP HTTP”.² Each word in the vocabulary V is represented by a D dimensional vector in a shared look-up table $L \in \mathbb{R}^{|V| \times D}$. L is considered a model parameter to be learned. We can initialize L randomly or using pretrained word embedding vectors like word2vec [13].

Given an input tweet $s = (w_1, \dots, w_T)$, we first transform it into a feature sequence by mapping each word token $w_t \in s$ to an index in L . The look-up layer then creates an input vector $\mathbf{x}_t \in \mathbb{R}^D$ for each token w_t , which are passed through a sequence of convolution and pooling operations to learn high-level feature representations.

A convolution operation involves applying a *filter* $\mathbf{u} \in \mathbb{R}^{L \times D}$ (i.e., a vector of parameters) to a window of L words to produce a new feature

$$h_t = f(\mathbf{u} \cdot \mathbf{x}_{t:t+L-1} + b_t) \quad (1)$$

where $\mathbf{x}_{t:t+L-1}$ denotes the concatenation of L input vectors, b_t is a bias term, and f is a nonlinear activation

²HTTP represents URLs present in a tweet.

function (e.g., sig, tanh). A filter is also known as a kernel or feature detector. We apply this filter to each possible L -word window in the tweet to generate a *feature map* $\mathbf{h}^i = [h_1, \dots, h_{T+L-1}]$. We repeat this process N times with N different filters to get N different feature maps (i.e., $i = 1 \dots N$). We use a *wide* convolution [14] (as opposed to *narrow*), which ensures that the filters reach the entire sentence, including the boundary words. This is done by performing *zero-padding*, where out-of-range (i.e., $t < 1$ or $t > T$) vectors are assumed to be zero.

After the convolution, we apply a max-pooling operation to each feature map.

$$\mathbf{m} = [\mu_p(\mathbf{h}^1), \dots, \mu_p(\mathbf{h}^N)] \quad (2)$$

where $\mu_p(\mathbf{h}^i)$ refers to the max operation applied to each window of p features in the feature map \mathbf{h}^i . For instance, with $p = 2$, this pooling gives the same number of features as in the feature map (because of the zero-padding). Intuitively, the filters compose local n -grams into higher-level representations in the feature maps, and max-pooling reduces the output dimensionality while keeping the most important aspects from each feature map.

Since each convolution-pooling operation is performed independently, the features extracted become invariant in locations (i.e., where they occur in the tweet), thus acts like bag-of- n -grams. However, keeping the *order* information could be important for modeling sentences. In order to model interactions between the features picked up by the filters and the pooling, we include a *dense* layer of hidden nodes on top of the pooling layer

$$\mathbf{z} = f(V\mathbf{m} + \mathbf{b}_h) \quad (3)$$

where V is the weight matrix, \mathbf{b}_h is a bias vector, and f is a non-linear activation. The dense layer naturally deals with variable sentence lengths by producing fixed size output vectors \mathbf{z} , which are fed to the output layer for classification.

Depending on the classification task, the output layer defines a probability distribution. For binary classification task, it defines a Bernoulli distribution:

$$p(y|s, \theta) = \text{Ber}(y | \text{sig}(\mathbf{w}^T \mathbf{z} + b)) \quad (4)$$

where sig refers to the sigmoid function, and \mathbf{w} are the weights from the dense layer to the output layer and b is a bias term. For multi-class classification the output layer uses a softmax function. Formally, the probability of k -th label in the output for classification into K classes:

$$P(y = k | \mathbf{s}, \theta) = \frac{\exp(\mathbf{w}_k^T \mathbf{z} + b_k)}{\sum_{j=1}^K \exp(\mathbf{w}_j^T \mathbf{z} + b_j)} \quad (5)$$

where, \mathbf{w}_k are the weights associated with class k in the output layer. We fit the models by minimizing the cross-entropy

between the predicted distributions $\hat{y}_{n\theta} = p(y_n | \mathbf{s}_n, \theta)$ and the target distributions y_n (i.e., the gold labels).³

$$J(\theta) = \sum_{n=1}^N \sum_{k=1}^K y_{nk} \log P(y_n = k | \mathbf{s}_n, \theta) \quad (6)$$

where, N is the number of training examples and $y_{nk} = I(y_n = k)$ is an indicator variable to encode the gold labels, i.e., $y_{tk} = 1$ if the gold label $y_t = k$, otherwise 0.

A. Word Embedding and Fine-tuning

We avoid manual engineering of features and use word embeddings instead as the only features. As mentioned before, we can initialize the embeddings L randomly, and learn them as part of model parameters by backpropagating the errors to the look-up layer. Random initialization may lead the training algorithm to get stuck in local minima. One can plug the readily available embeddings from external sources (e.g., Google embeddings [13]) in the neural network model and use them as features without further task-specific tuning. However, this approach does not exploit the automatic feature learning capability of NN models, which is one of the main motivations of using them. In our work, we use the pre-trained word embeddings to better initialize our models, and we fine-tune them for our task which turns out to be beneficial. More specifically, we initialize the word vectors in L in two different ways.

1. Google Embedding: Mikolov et al. [13] propose two log-linear models for computing word embeddings from large (unlabeled) corpus efficiently: (i) a *bag-of-words* model CBOW that predicts the current word based on the context words, and (ii) a *skip-gram* model that predicts surrounding words given the current word. They released their pre-trained 300-dimensional word embeddings (vocabulary size 3 million) trained by the skip-gram model on part of Google news dataset containing about 100 billion words.⁴

2. Crisis Embedding: Since we work on disaster related tweets, which are quite different from news, we have also trained *domain-specific* embeddings (vocabulary size 20 million) using the Skip-gram model of *word2vec* tool [11] from a large corpus of disaster related tweets. The corpus contains 57,908 tweets and 9.4 million tokens. For comparison with Google, we learn word embeddings of 300-dimensions.

B. Incorporating Other Features

Although CNNs learn word features (i.e., embeddings) automatically, we may still be interested in incorporating other sources of information (e.g., TF-IDF vector representation of tweets) to build a more effective model. Additional features can also guide the training to learn a better model.

³Other loss functions (e.g., hinge) yielded similar results.

⁴<https://code.google.com/p/word2vec/>

However, unlike word embeddings, we want these features to be fixed during training. This can be done in our CNN model by creating another channel, which feeds these additional features directly to the *dense* layer. In that case, the dense layer in Equation 3 can be redefined as

$$\mathbf{z} = f(V' \mathbf{m}' + \mathbf{b}_h) \quad (7)$$

where $\mathbf{m}' = [\mathbf{m}; \mathbf{y}]$ is a concatenated (column) vector of feature maps \mathbf{m} and additional features \mathbf{y} , and V' is the associated weight matrix. Notice that by including this additional channel, this network combines a multi-layer perceptron (MLP) with a CNN model.

III. DOMAIN ADAPTATION

Since DNNs usually have far more parameters than non-neural models, it is often advantageous to train DNNs with lots of data. When comes to big crisis data, one straightforward approach is to use all available data both from the current event as well as from all past events. However, due to a number of reasons such as, variety of data in different crisis events, different language usage, differences in vocabulary [15], not all labeled crisis data from past events are useful for classifying event under consideration. In fact in our experiments we found more data but irrelevant degrades the performance of the model. Based on this observation, we apply two domain adaptation techniques that make the best use of the out-of-event data in favor of the event data by either weighing the out-of-event data or intelligently selecting a subset of the out-of-event data. Both methods are described as follows.

A. 1. Regularized Adaptation Model:

Our first approach is to learn an adapted model from the complete data but to regularize the resultant model towards the event data. Let θ_i be a CNN model already trained on the event data. We train an adapted model θ_a on the complete in- and out-of-event data, but regularizing it with respect to the in-domain model θ_i . Formally, we redefine the loss function of Equation 6 as follows:

$$J(\theta_a) = \sum_{n=1}^N \sum_{k=1}^K \left[\lambda y_{nk} \log P(y_n = k | \mathbf{s}_n, \theta_a) + (1 - \lambda) y_{nk} P(y_n = k | \mathbf{s}_n, \theta_i) \log P(y_n = k | \mathbf{s}_n, \theta_a) \right] \quad (8)$$

where $P(y_n = k | \mathbf{s}_n, \theta_i)$ is the probability of the training instance (\mathbf{s}_n, y_n) according to the event model θ_i . Notice that the loss function minimizes the cross entropy of the current model θ_a with respect to the gold labels y_n and the event model θ_i . The mixing parameter $\lambda \in [0, 1]$ determines the relative strength of the two components.⁵ Similar adaptation model has been used previously in neural models for machine translation [16], [17].

⁵We used a balanced value $\lambda = 0.5$ for our experiments.

B. 2. Instance Selection:

Similar to the regularized adaptation model, we use an event only classifier to predict the labels of the out-of-event instances. Instead of using probabilities as weights, we select only those out-of-event tweets which are predicted correctly by the event-based classifier. We concatenate the selected out-of-event tweets to the event data and train a classifier. This method is similar in spirit to the method proposed by Jiang and Zhai [18].

IV. EXPERIMENTAL SETTINGS

In this section, we first describe the dataset used for the classification tasks. We then present the TF-IDF based features which are used to train the non-neural classification algorithms and used a additional features for the MLP-CNN model. In the end, we describe the training settings of non-neural and neural classification models.

A. Datasets

We use data from multiple sources: (1) CrisisNLP [19], (2) CrisisLex [20], and (3) AIDR [8]. The first two sources have tweets posted during several humanitarian crises and labeled by paid workers. The AIDR data consists of tweets from several crises events labeled by volunteers.⁶

The dataset consists of various event types such as earthquakes, floods, typhoons, etc. In all the datasets, the tweets are labeled into various informative classes (e.g., urgent needs, donation offers, infrastructure damage, dead or injured people) and one not-related or irrelevant class. Table I provides a one line description of each class and also the total number of labels from all the sources. *Other useful information* and *Not related or irrelevant* are the most frequent classes in the dataset. Table II shows statistics about the events we use for our experiments.

In order to access the difficulty of the classification task, we calculate the inter-annotator agreement (IAA) scores of the datasets obtained from CrisisNLP. The California Earthquake has the highest IAA of 0.85 and Typhoon Hagupit has the lowest IAA of 0.70 in the events under-consideration. The IAA of remaining three events are around 0.75. We aim to reach these levels of accuracy.

Data Preprocessing: We normalize all characters to their lower-cased forms, truncate elongations to two characters, spell out every digit to `D`, all twitter usernames to `USERID`, and all URLs to `HTTP`. We remove all punctuation marks except periods, semicolons, question and exclamation marks. We further tokenize the tweets using the CMU TweetNLP tool [21].

Data Settings: For a particular event such as Nepal earthquake, data from all other events plus *All others* (see

⁶These are trained volunteers from the Stand-By-Task-Force organization (<http://blog.standbytaskforce.com/>).

Class	Labels	Description
Affected individual	6,418	Reports of deaths, injuries, missing, found, or displaced people
Donations and volunteering	3,683	Messages containing donations (food, shelter, services etc.) or volunteering offers
Infrastructure and utilities	3,288	Reports of infrastructure and utilities damage
Sympathy and support	6,178	Messages of sympathy-emotional support
Other useful information	14,696	Messages containing useful information that does not fit in one of the above classes
Not related or irrelevant	15,302	Irrelevant or not informative, or not useful for crisis response

Table I: Description of the classes in the datasets. Column *Labels* shows the total number of annotations for each class

EVENT	Nepal Earthquake	Typhoon Hagupit	California Earthquake	Cyclone PAM	All Others
Affected individual	756	204	227	235	4624
Donations and volunteering	1021	113	83	389	1752
Infrastructure and utilities	351	352	351	233	1972
Sympathy and support	983	290	83	164	4546
Other Useful Information	1505	732	1028	679	7709
Not related or irrelevant	6698	290	157	718	418
Grand Total	11314	1981	1929	2418	21021

Table II: Class distribution of events under consideration and all other crises (i.e. data used as part of *out-of-event* data)

Table II) is considered as *out-of-event* data. We divide each event dataset into train (70%), validation (10%) and test sets (20%) using *ski-learn* toolkit’s module [22] which ensured that the class distribution remains reasonably balanced in each subset.

Feature Extraction: We extracted unigram, bigram and trigram features from the tweets as features. The features are converted to TF-IDF vectors by considering each tweet as a document. Note that these features are used only in non-neural models. The neural models take tweets and their labels as input. For SVM classifier, we implemented feature selection using Chi Squared test to improve estimator’s accuracy scores.

B. Non-neural Model Settings

To compare our neural models with the traditional approaches, we experimented with a number of existing models including: (i) Support Vector Machine (SVM), a discriminative max-margin model; (ii) Logistic Regression (LR), a discriminative probabilistic model; and (iii) Random Forest (RF), an ensemble model of decision trees. We use the implementation from the *scikit-learn* toolkit [22]. All algorithms use the default value of their parameters.

C. Settings for Convolutional Neural Network

We train CNN models by optimizing the cross entropy in Equation 4 using the gradient-based online learning algorithm ADADELTA [23].⁷ The learning rate and parameters were set to the values as suggested by the authors. Maximum number of epochs was set to 25. To avoid overfitting, we use dropout [24] of hidden units and *early stopping* based on the accuracy on the validation set.⁸ We experimented with

{0.0, 0.2, 0.4, 0.5} dropout rates and {32, 64, 128} mini-batch sizes. We limit the vocabulary (V) to the most frequent $P\%$ ($P \in \{80, 85, 90\}$) words in the training corpus. The word vectors in L were initialized with the pre-trained embeddings. See Section II-A.

We use rectified linear units (ReLU) for the activation functions (f), {100, 150, 200} filters each having window size (L) of {2, 3, 4}, pooling length (p) of {2, 3, 4}, and {100, 150, 200} dense layer units. All the hyperparameters are tuned on the development set.

V. RESULTS

For each event under consideration, we train classifiers on the event data only, on the out-of-event data only, and on a combination of both. We evaluate them for the binary and multi-class classification tasks. For the former, we merge all informative classes to create one general *Informative* class.

We initialized the CNN model using two types of pre-trained word embeddings. (i) *Crisis Embeddings*⁹ CNN_I : trained on all crisis tweets data (ii) *Google Embeddings* CNN_{II} trained on the Google News dataset. The CNN model then fine-tuned¹⁰ the embeddings using the training data.

A. Binary Classification

Table III (left) presents the results of binary classification comparing several non-neural classifiers with the CNN-based classifier. CNNs performed better than all non-neural classifiers for all events under consideration. The improvements are substantial in the case of training with the out-of-event data only. In this case, CNN outperformed SVM by a margin of up to 11%. This result has a significant impact to a situation involving early hours of a crisis, where though

⁷Other algorithms (SGD, Adagrad) gave similar results.

⁸ l_1 and l_2 regularization on weights did not work well.

⁹Using *word2vec* with the *Skip-gram* method [13] and *context* of size 6

¹⁰We experimented with fixed embeddings but they did not perform well.

a lot of data pours in, but performing data labeling using experts or volunteers to get a substantial amount of training data takes a lot of time. Our result shows that the CNN model handles this situation robustly by making use of the out-of-event data and provides reasonable performance.

When trained using both the event and out-of-event data, CNNs also performed better than the non-neural models. Comparing different training settings, we saw a drop in performance when compared to the event-only training. This is because of the inherent variety in the big crisis data. The large size of the out-of-event data down-weights the benefits of the event data, and skewed the probability distribution of the training data towards the out-of-event data.

Table III (right) presents the confusion matrix of the SVM and CNN_I classifiers trained and evaluated on the Nepal earthquake data. The SVM prediction is inclined to favor the Informative class whereas CNN predicted more instances as non-informative than informative. In the case of out-of-event training, SVM predicted most of the instances as informative. Thus, it achieved high recall, but very low precision. CNN, on the other hand, achieved quite balanced precision and recall numbers.

To summarize, the neural network based classifier outperformed non-neural classifiers in all data settings. The performance of the models trained on out-of-event data are (as expected) lower than that in the other two training settings. However, in case of the CNN models, the results are reasonable to the extent that out-of-event data can be used to predict tweets informativeness when no event data is available. Comparing CNN_I with CNN_{II}, we did not see any system consistently better than the other. In the rest of

our experiments below, we only consider the CNN_I trained on crisis embedding because on the average, the crisis embedding works slightly better than the other alternative.

B. Multi-class Classification

For the purpose of multi-class classification, we mainly compare the performance of two variations of the CNN-based classifier, CNN_I and MLP-CNN_I (combining multi-layer perception and CNN), against an SVM classifier. Table IV summarizes the accuracy and macro-F1 scores. In addition to the results on event, out-of-event and event+out, we also show the results for the adaptation methods described in Section III; see the rows with M_{event+adpt01} and M_{event+adpt02} system names. Similar to the results of the binary classification task, the CNN model outperformed the SVM model in all data settings. Combining MLP and CNN improved the performance of our system significantly. The results on training with both event and out-of-event data did not have a clear improvement over training on the event data only. The results dropped slightly in some cases.

When applied regularized adaptation model (M_{event+adpt01}) to adapt the out-of-event data in favor of the event data, the system shows mixed results. Since the adapted model is using the complete out-of-event data for training, we hypothesized that weighting does not completely balance the effect of the out-of-event data in favor of the event data. In the instance selection adaptation method (M_{event+adpt02}), we select items of the out-of-event data that are correctly predicted by the event-based classifier and use them to build an event plus out-of-event classifier. The results improved in all cases. We expect that a better

adaptation method can further improve the classification results which is out of the scope of this work.

VI. DISCUSSION

Time-critical analysis of big crisis data posted online especially during the onset of a crisis situation requires real-time processing capabilities (e.g. real-time classification of messages). Big crisis data is voluminous and has a lot of variety due to *noise*. Thus, we need to filter out the noise first using a binary (Informative/Non-Informative) classifier and then use the Informative data for humanitarian purposes.

To fulfill different information needs of humanitarian responders, we have also presented the results obtained from the multi-class classification task. In that case, we used a number of classes useful for humanitarian assistance. Generally the neural network classifiers performed better than the non-neural classifiers. We further showed improvements by doing domain adaptation where the instance selection approach outperformed among all neural network classifiers. This is due to the reason that the instance selection helps remove noise from out-of-event labeled data.

In Figure 2, we show precision-recall curves obtained from MLP-CNN_I models that outperform the other models in most of the cases and in Figure 3 class distribution of the training data used in these models is depicted. California, Hagupit, and PAM seem to be easier datasets than Nepal as evidenced by more area under the curve for the

former datasets than in Nepal across different classes. The accuracies of the different classes for the different events seem to have been influenced somewhat by the number of available training samples. The areas under the curve for the Nepal earthquake are the lowest implying that it is the hardest event dataset for the classification task. Interestingly, the Not-Relevant Class is the easiest to identify and has the highest AUC in Nepal (that class has almost 50% of the tweets for this event) and the lowest AUC in the California event datasets (consistent with the fact that that class has less than 10% of the tweets for this event). All the other classes have higher AUCs in the California dataset than the Nepal dataset implying California is easier to classify for our classifier. In Typhoon Hagupit, the not-informative class again has the lowest AUC (about 15% of the tweets are in this class) and the pattern is similar to that in the California event dataset. But in Cyclone Pam dataset, the Not-Relevant class has greater AUC and the Sympathy (which is the smallest class), Other (which actually has 30% support), and Infrastructure classes (around 10% support) have the lowest AUCs.

Generally, the classes with the smallest percentage of tweets have lower AUCs, but that is not always the case. We conjecture that a combination of the amount of training data and the inherent hardness related to classifying a class combine to make a class harder or easier to classify. Another factor that we did not consider in this work is the semantic

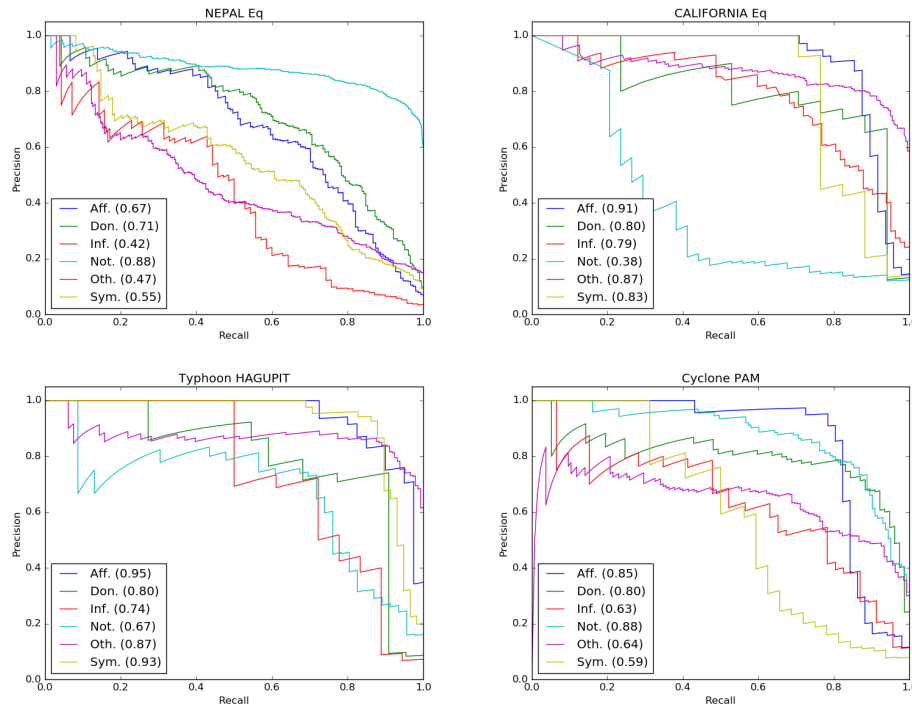

Figure 2: Precision-Recall curves and AUC scores of each class generated from $MLP-CNN_I$ and $M_{event+adapt02}$ models

Figure 3: Heatmap shows class distribution of training data for each event used to train the $M_{event+adapt02}$ models

relatedness of a tweet under several classes which brings inconsistency in labeling. Evaluation of the classifiers based on top N probable classes can shed light into this [25] where N is the total number of classes in the dataset.

VII. RELATED WORK

Studies have analyzed how big crisis data can be useful during major disasters so as to gain insight into the situation as it unfolds [6], [26], [27]. A number of systems have been developed to classify, extract, and summarize crisis-relevant information from social media; for a detailed survey see [5]. Cameron, et al., describe a platform for emergency situation awareness [28]. They classify interesting tweets

using an SVM classifier. Verma, et al., use Naive Bayes and MaxEnt classifiers to find situational awareness tweets from several crises [29]. Imran, et al., implemented AIDR to classify a Twitter data stream during crises [8]. They use a random forest classifier in an offline setting. After receiving every minibatch of 50 training examples, they replace the older model with a new one. In [30], the authors show the performance of a number of non-neural network classifiers trained on labeled data from past crisis events. However, they do not use DNNs in their comparison.

DNNs and word embeddings have been applied successfully to address NLP problems [31], [9], [32]. The emergence of tools such as word2vec [11] and GloVe [33] have enabled NLP researchers to learn word embeddings efficiently and use them to train better models.

Collobert, et al. [9] presented a unified DNN architecture for solving various NLP tasks including part-of-speech tagging, chunking, named entity recognition and semantic role labeling. They showed that DNNs outperform traditional models in most of these tasks. They also proposed a multi-task learning framework for solving the tasks jointly.

Kim [34] and Kalchbrenner et al. [14] used convolutional neural networks (CNN) for sentence-level classification tasks (e.g., sentiment/polarity classification, question classification) and showed that CNNs outperform traditional methods (e.g., SVMs, MaxEnts). Despite these recent advancements, the application of CNNs to disaster response is novel to the best of our knowledge.

VIII. CONCLUSION AND FUTURE WORK

We addressed the problem of rapid classification of crisis-related data posted on microblogging platforms like Twitter. Specifically, we addressed the challenges using deep neural network models for binary and multi-class classification tasks and showed that one can reliably use out-of-event data for the classification of new event when no event-specific data is available. The performance of the classifiers degraded from event data when out-of-event training samples were added to training samples. Thus, we recommend using out-of-event training data during the first few hours of a disaster only after which the training data related to the event should be used. We improved the performance of the system using domain adaptation by either regularized adaptation and instance selection.

In the future, we will explore and perform experimentation to determine even more robust domain adaptation techniques. Moreover, addressing the variety in the data by segregating code mixing of multiple languages in the same tweet needs additional work. Identifying topic evolution in big crisis data during an event can help us be aware of the variability of such data. All of these modules can be built on top of our classification system and work in concert with it.
